

# Uncertainty in Computer Models – Part 2

Tony O'Hagan

# Outline

- ▲ Gaussian processes
- ▲ Practical issues in emulator construction
- ▲ Calibration
- ▲ Dynamic models

# Gaussian processes

# GP basics

- ▲ A Gaussian process is a probability distribution for a function  $f(x)$ 
  - ▲ It is a mathematically convenient distribution for our purposes
- ▲ It says that
  - ▲  $f(x)$  is normally distributed for every  $x$
  - ▲  $f(x_1), f(x_2), \dots, f(x_n)$  are jointly normally distributed for any set of  $x_1, x_2, \dots, x_n$
- ▲ The GP is specified by giving
  - ▲ A mean function  $m(x) = E(f(x))$
  - ▲ A covariance function  $c(x, x') = \text{cov}(f(x), f(x'))$

# GP as a prior distribution

- ▲ We use a GP to represent prior beliefs about the computer model  $f(x)$ 
  - ▲ Formally, this is belief about the model prior to making any runs
  - ▲  $m(x)$  is our prior expectation of  $f(x)$
  - ▲  $c(x,x) = \text{var}(f(x))$  describes our uncertainty about  $f(x)$
  - ▲  $c(x,x')$  describes correlation between points  $x$  and  $x'$ 
    - ▲ And so represents how smooth the function is
- ▲ In practice, we rarely have detailed prior knowledge of this kind
  - ▲ Instead, we express prior information just through the general shape of these functions

# Hierarchical modelling – $m(x)$

- ▲ Prior information about the general way in which  $f(x)$  responds to the inputs  $x$  is expressed in a linear modelling form
  - ▲  $m(x) = \beta'h(x)$
  - ▲ where  $h(x)$  is a vector of known functions and  $\beta$  is a vector of unknown regression parameters
- ▲ For instance, we often set
  - ▲  $h(x) = (1, x)'$
  - ▲ This expresses a prior expectation that the model will respond roughly linearly to each input
  - ▲ Then the  $\beta$  vector comprises the intercept and slope of the response to each input

# Hierarchical modelling – $c(x,x')$

- ▲ The covariance function defines uncertainty and correlation
- ▲ The usual formulation is
  - ▲  $c(x,x') = \sigma^2 \exp\{-(x-x')'V(x-x')\}$
  - ▲ where  $\sigma^2$  is a variance parameter and  $V$  is a matrix of parameters controlling correlation
- ▲ In turn, we usually assume  $V$  is diagonal, so that there is a correlation parameter for each input
- ▲ There are other covariance functions that are sometimes used
  - ▲ This form implies that  $f(x)$  is differentiable

# Hyperparameter distributions

- ▲ In this hierarchical framework, we next need to supply distributions for the “hyperparameters”
  - ▲  $\beta$ ,  $\sigma^2$  and (the diagonal elements of)  $V$
- ▲ Informative prior distributions may be elicited to express genuine knowledge
  - ▲ For instance, by talking to the modellers
- ▲ In practice, we generally assume vague prior distributions for all the hyperparameters

# The emulator

- ▲ Having set up the GP prior distribution, we use the model runs to train it
- ▲ The resulting posterior distribution is the emulator
  - ▲ Conditional on the hyperparameters, the posterior is a GP
    - ▲ But with more complex mean and covariance structure reflecting the training data
  - ▲ The training runs are also used to update the distributions for the hyperparameters
    - ▲ This is typically rather complex for the correlation parameters in  $V$

# Practical issues in emulator construction

# Smoothness

- ▲ It is the basic assumption of a (homogeneously) smooth, continuous function that gives the GP its computational advantages
- ▲ The actual degree of smoothness concerns how rapidly the function “wiggles”
  - ▲ Which in turn is controlled by the correlation length parameters
- ▲ A rough function responds strongly to quite small changes in inputs
- ▲ We need many more data points to emulate accurately a rough function over a given range

# Effect of correlation length

- ▲ These parameters determine how fast the uncertainty increases between data points
  - ▲ High correlation length = high smoothness

# Higher dimensions

- ▲ With 2 inputs, we are fitting a surface through the data
- ▲ With many inputs, the principles are the same
  - ▲ Correlation length parameters (one for each dimension, usually) are crucial
  - ▲ Estimation can be difficult, though
- ▲ In many dimensions there is much more “space” between data points
  - ▲ But we also get more smoothness

# Automatic screening

- ▲ Models never respond strongly to all their inputs
- ▲ Pragmatically, we get a high level of smoothness except in a few dimensions
- ▲ By estimating correlation parameters, the GP automatically adjusts
  - ▲ Effectively it projects points down through smooth dimensions
  - ▲ 200 points in 25 dimensions look sparse
  - ▲ But in 5 dimensions they are pretty good
- ▲ Models with hundreds or thousands of inputs still pose big computational problems

# Design

- ▲ We need to choose input configurations at which to run the model to get training data
  - ▲ They don't need to be random
- ▲ The objective is to learn about the function
- ▲ We need well spaced points that cover the region of interest
- ▲ E.g. generate 100 random Latin Hypercube samples and choose the one having largest minimum distance between points

# Computational challenges

- ▲ Many inputs
  - ▲ Need to estimate many correlation parameters
  - ▲ Searching the space of correlation parameters becomes computationally burdensome
- ▲ Many training runs
  - ▲ The method requires inversion of a variance matrix whose dimension is the number of runs
  - ▲ This matrix can easily become ill-conditioned with the usual covariance structure
- ▲ These problems typically arise together

# Inhomogeneity and discontinuity

- ▲ The GP assumes homogeneous smoothness and variance properties across the input space
  - ▲ Many models have regions of input space where the model behaves differently from others
  - ▲ Some models do not vary continuously as the inputs are varied
- ▲ In such cases the GP emulator may not fit well

# Calibration

# Traditional calibration

- ▲ Calibration is the process of using observational data to learn about uncertain parameters/inputs in the model
- ▲ Traditional approach:
  - ▲ Adjust the parameters until the model outputs come as close as possible to the observed data
  - ▲ Set the parameters to those best fitting values, acting as if they are now known
- ▲ Deficiencies:
  - ▲ Ignores uncertainty in fitted parameters
  - ▲ Often, best fitting parameter values are implausible

# Models and reality

## ▲ Notation:

- ▲ Inputs  $x = (c, t)$  comprise control inputs  $c$  and uncertain parameters  $t$
- ▲ We have  $n$  observations of the real process yielding data

$$z_j = \zeta(c_j) + \varepsilon_j, \text{ for } j = 1, 2, \dots, n$$

- ▲ Relationship between model and reality

$$\zeta(c) = f(c, \theta) + \delta(c)$$

## ▲ The model discrepancy term $\delta(c)$ is crucial

- ▲ Model output does not equal reality, even when we use the best values  $\theta$  of the uncertain parameters  $t$

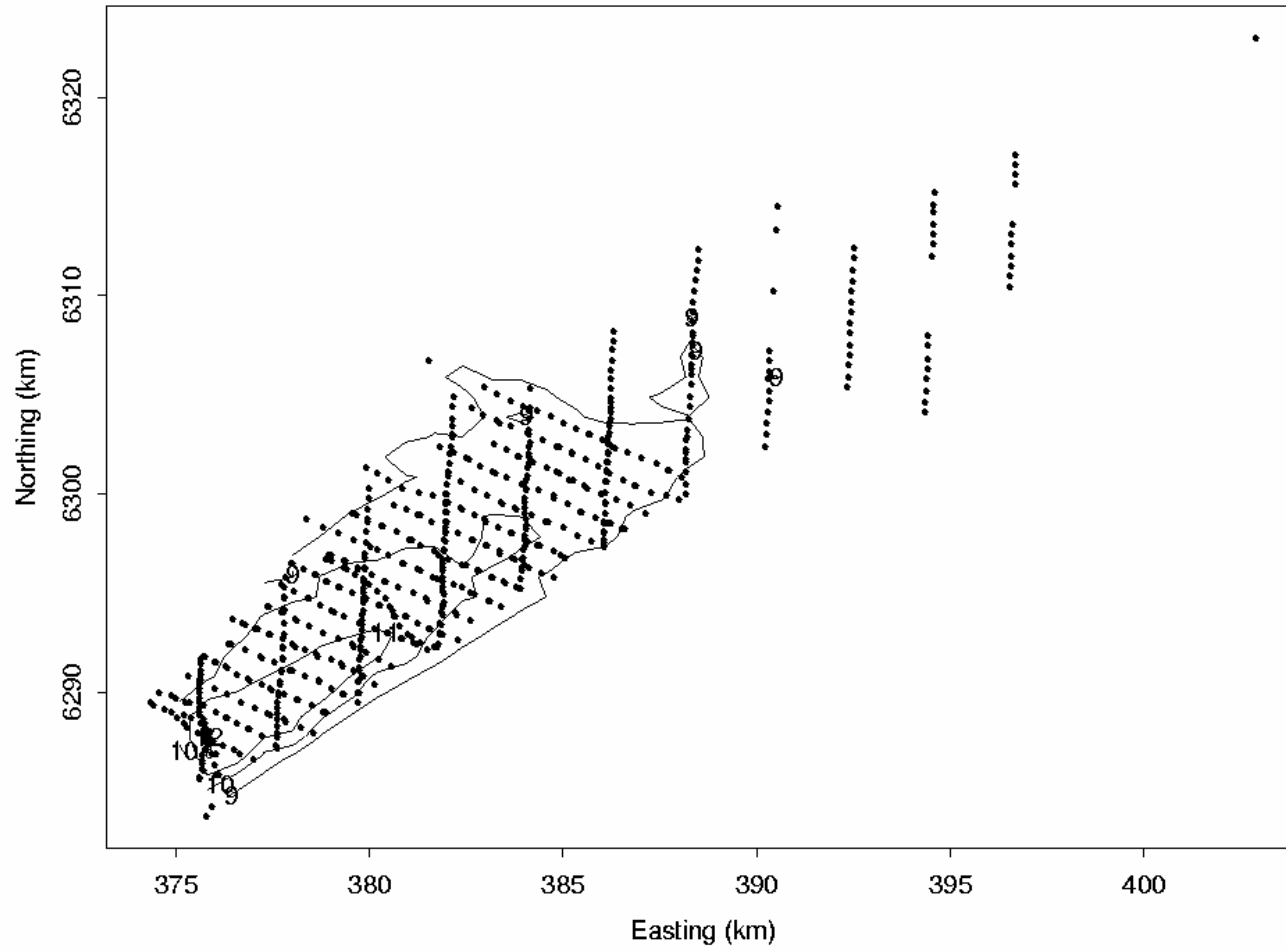

# Bayesian method

- ▲ Model  $\delta(c)$  as another GP
- ▲ Use observational data to learn about both  $\delta(c)$  and  $\theta$ 
  - ▲ If the computer model is computationally intensive, we may also need to emulate  $f(x)$
- ▲ Predictions of the real process allow for remaining uncertainty in  $\theta$ ,  $\zeta(c)$ 
  - ▲ and  $f(x)$  if we have to emulate it
  - ▲ and  $c$  if appropriate

# Example: Nuclear accident

- ▲ Radiation was released after an accident at the Tomsk-7 chemical plant in 1993
- ▲ Data comprise measurements of the deposition of ruthenium 106 at 695 locations obtained by aerial survey after the release
- ▲ The computer code is a simple Gaussian plume model for atmospheric dispersion
- ▲ Two calibration parameters
  - ▲ Total release of  $^{106}\text{Ru}$  (source term)
  - ▲ Deposition velocity

# Data

# Calibration

- ▲ A small sample ( $N=10$  to  $25$ ) of the 695 data points was used to calibrate the model
- ▲ Then the remaining observations were predicted and RMS prediction error computed

<i>Sample size <math>N</math></i>	<i>10</i>	<i>15</i>	<i>20</i>	<i>25</i>
Best fit calibration	0.82	0.79	0.76	0.66
Bayesian calibration	0.49	0.41	0.37	0.38

- ▲ On a log scale, error of 0.7 corresponds to a factor of 2

# Emulating dynamic models

# Dynamic models

- ▲ Initial state  $x_0$  is updated recursively by the one-step model  $f_1(x, c)$
- ▲ Forcing inputs  $c_t$
- ▲ Interested in sequence  $x_1, x_2, \dots, x_T$
- ▲ At least 4 approaches to emulating this

# 1. Treat time as input

- ▲ Emulate  $x_t$  as the function

$$\begin{aligned} f(x_0, t) &= f_t(x_0, \mathbf{c}^t) = f_1(x_{t-1}, c_t) \\ &= f_1(\dots f_1(f_1(x_0, c_1), c_2) \dots, c_t) \end{aligned}$$

- ▲ Easy to do
- ▲ Hard to get the temporal correlation structure right

## 2. Multivariate emulation

- ▲ Emulate the vector  $\mathbf{x} = (x_1, x_2, \dots, x_T)$  as the multi-output function

$$\mathbf{f}_T(x_0) = (f_1(x_0, \mathbf{c}^1), f_2(x_0, \mathbf{c}^2), \dots, f_T(x_0, \mathbf{c}^T))$$

- ▲ Simple extension of univariate theory
- ▲ Restrictive covariance structure

# 3. Functional output emulation

- ▲ Treat  $x$  series as a functional output
- ▲ Identify features (e.g. principal components) to summarise function
- ▲ Same theory as for multivariate emulation, but lower dimension
- ▲ Loss of information, no longer reproduces training data

# 4. Recursive emulation

- ▲ Emulate the single step function

$$f_1(x, c)$$

- ▲ Iterate the emulator numerically
  - ▲ May take longer than original model!
- ▲ Or approximate filtering algorithm
  - ▲ May be inaccurate for large  $T$

# Some comparisons

- ▲ Multivariate emulation (approach 2) is better than treating time as an input (approach 1)
  - ▲ Validates better
  - ▲ Able to work with partial series
- ▲ Recursive emulation still under development
  - ▲ Looking promising
- ▲ Only recursive emulation can realistically treat uncertainty in forcing inputs
- ▲ Only recursive emulation can extend  $T$  beyond training data
